

Introduction

The purpose of this study was to evaluate a new intervention for a common condition, building on prior work by Smith and colleagues [1]. We hypothesized that the intervention would outperform standard care across several outcome measures, and designed a trial to test this directly.

Background

Prior studies have been limited by small sample sizes and short follow-up periods, leaving important questions about long-term benefit unanswered.

Methods

Participants were randomly assigned to one of two groups. The primary outcome was assessed at twelve weeks by a rater blinded to group assignment, using a validated instrument with well-established reliability.
